## Abstract

In this report we explore the feasibility of using a 4U CubeSat to image the zodiacal dust cloud from a face-on perspective above the ecliptic plane. To do this, trade studies and analyses of various subsystem components were performed to ensure each subsystem could meet the requirements of this mission. Within two semesters we were able to complete this feasibility analysis for all subsystems and determine that this ZODI mission could be accomplished with a 4U CubeSat.

## 1 Introduction

The ZODI CubeSat Project Team's goal is to design, build, and launch a CubeSat tasked with detaching from a larger payload, getting at least 0.10AU above the elliptic disk, taking face-on photographs of the Zodiacal Dust Cloud, then transmitting that data back to Earth. Over the course of the Fall 2017 and Spring 2018 terms, analysis was performed in order to assess the feasibility of accomplishing this task with a CubeSat less than 6U in size.

Our current flight trajectory was simulated and put forth by Gabriel Soto in his paper "Optimization of high-inclination orbits using planetary flybys for a zodiacal light-imaging mission" [1], in which he proposes using the EVE transfer maneuver originally proposed for the 2022 Europa Clipper mission as a jumping-off point for a zodiacal light imaging CubeSat mission. Following his analysis, deploying from the Europa Clipper after the Venus flyby of its EVE maneuver, 68% of the way to the next flyby of Earth, a single  $\Delta v$  burn of 37.21m/s in conjunction with the resulting Earth gravity assist would produce an elliptic orbit with apoapsis 0.22 AU above the solar elliptic disk and periapsis 0.13AU below the solar elliptic disk. This orbit will have an orbital period of one Earth year (365.1653 day orbital period), ensuring it will intercept the Earth a year later with a closest approach of 8371km.

A potentially different trajectory utilizing solar sails was researched by Amlan Sinha in the Fall 2017 semester, but was ultimately not selected. The infancy of solar sail technology as well as difficulties getting the CubeSat back into Earth transmission range ultimately resulted in the decision to choose the previously mentioned EVE method to achieve our desired orbital height.

Through this year-long analysis, we have concluded that a 4U CubeSat will be sufficient to complete this mission. Below in Figure 1, a CAD model of our Zodi CubeSat design while fully deployed is shown. Figure 2 shows a preliminary arrangement of the Zodi CubeSat interior.

Figure 1: CAD model of our Zodi CubeSat fully deployed. See Figure 2 for internal view.

## 2 Mission Overview

## 2.1 Mission Requirements

Requirement ID	System-Level Requirements
REQ 1	The CubeSat must be below 6U in volume
REQ 2	The CubeSat must be able to accomplish all mission goals autonomously after
	deployment
REQ 3	The CubeSat must reach a height of at least 0.1AU above the ecliptic in order to
	properly image the zodiacal cloud
REQ.4	The CubeSat must be able to capture at least one full horizon of images
REQ 5	The CubeSat must be able to operate for a 1 Earth year lifecycle after deployment
	until data collection and transmission is completed
REQ 6	The CubeSat must be able to store all collected data onboard until transmission
	approximately 1 Earth year after deployment
REQ 7	The CubeSat must be able to transmit all collected data back to Earth

Table 1: System-Level Requirements for the Zodi CubeSat Mission

### 2.2 Mission Storyboard

### Event 1: Launch & Transit (Undeployed)

The Zodi CubeSat will be housed in a 4U CubeSat deployment pod attached to the body of the Europa Clipper inside the launch vehicle fairing. Both the CubeSat and deployment pod will be designed to handle the gravitational, thermal, and vibrational loads associated with the specific launch vehicle. After exiting Earth's atmosphere, the CubeSat will remain attached to the Europa clipper during the (first) Earth and Venus sections of its EVE gravitational assist maneuver until CubeSat deployment occurs at Event 2.

### Event 2: CubeSat Deployment & Initialization

After the Europa Clipper performs its Venusian gravitational assist, the Zodi CubeSat will jettison from its deployment pod and begin startup initialization. During this time it will initialize its electronic systems and deploy its deployable solar array and antenna. The resulting initialization and gyroscopic data will be transmitted for several hours using its omnidirectional X-Band antenna (Communications Subsystem detailed in Section 4.3). If possible, the Deep Space Network (DSN) will be used to monitor for and receive this transmission, allowing the ground crew to confirm whether or not deployment and/or electronic initialization was successful. If either were unsuccessful, the ground crew will have until the inclination change burn in Event 3 Zodi CubeSat (when the CubeSat has traveled 68% of the way back to Earth) to diagnose the problem and upload a software fix using the DSN.

In the case where DSN monitoring time cannot be acquired, it will be entirely up to the Zodi CubeSat's autonomous programming (Command & Data Handling Subsystem detailed in Section 4.4) to determine whether deployment and initialization has occurred successfully and attempt to fix the problem if it has not. The autonomous system will be designed to attempt to fix the most probable deployment and startup errors even in the case where DSN monitoring time CAN be acquired.

After a successful startup and/or fixing any errors in deployment and initialization. The CubeSat will proceed along its trajectory until it has traveled 68% of the way to Earth, at which time it will begin its inclination change burn in Event 3. While in transit, the CubeSat will charge its backup Li-Ion battery.

### Event 3: Inclination Change & Earth Gravity Assist

68% of the way to Earth, the CubeSat will fire its electrospray thruster (Propulsion Subsystem detailed in Section 4.2) and execute a single  $\Delta v$  burn of 37.21m/s. The CubeSat will accomplish this burn using either the BET-1mN or BET-100 $\mu$ N electrospray thruster, completing the burn in 3.2 or 18.9 days, respectively. This burn, along with the final Earth gravity assist will increase the inclination of the Zodi CubeSat's orbit by an orbital height of 0.1283AU at periapsis, resulting in a final heliocentric orbit with periapsis located 0.1283AU below the ecliptic, apoapsis located 0.2215AU above the ecliptic, and an orbital period of approximately one Earth year. This orbital period will ensure that the CubeSat will re-intercept Earth one year later to transmit its scientific data. For a brief moment, the sun may be eclipsed by the Earth during this gravity assist. If an eclipse should occur, power will provided by the CubeSat's Li-Ion battery (Li-Ion Battery detailed in Section 4.5.2)

This final Earth gravitational assist also represents the first and last time that the ground crew will be able to contact the CubeSat without the need of the DSN until it returns to transmit its scientific data one year later. If DSN monitoring time could not be acquired in Event 2, the ground crew will have one last chance to receive startup data, diagnose any issues, and upload a software patch.

After completing its insertion into its final mission orbit, the CubeSat will begin transit to periapsis. It will take approximately 68.4208 days to reach periapsis. While in transit, the

CubeSat will enter a standby mode and recharge its backup Li-Ion battery to capacity.

### **Event 4: Image Collection at Periapsis**

Upon reaching periapsis, the Zodi CubeSat will begin face-on imaging of the Zodiacal Dust Cloud. This event represents the point at which the CubeSat will reach its highest temperature (Thermal Analysis detailed in Section 4.7). The solar array has been sized to provide sufficient power to the CubeSat subsystems during this imaging process without the need for a battery, though the Li-Ion battery will be able to provide additional power if necessary (Power Subsystem detailed in Section 4.5).

Upon nearing periapsis, the CubeSat will use its ACDS system to determine the direction of the Zodi Cloud and orient itself accordingly (ACDS Subsystem detailed in Section 4.6). To ensure the entire Zodi Cloud is imaged, the CubeSat's optical payload (Optical Payload detailed in Section 4.1) will capture the full horizon in 232 images. This imaging process will take 9.67 days. After each image is captured, it will be stored in the CubeSat's on-board harddrive and redundantly copied to protect the data from cosmic radiation bit flips (See Section 4.4).

After capturing and storing a full horizon of images, the Zodi CubeSat will reenter standby mode and recharge its Li-Ion battery if necessary. It will take approximately 172.9325 days for the CubeSat to reach the next event at apoapsis.

### **Event 5: Image Collection at Apoapsis**

Upon reaching apoapsis, the Zodi CubeSat will once again begin face-on imaging of the Zodiacal Dust Cloud. This event represents the point at which the CubeSat will reach its lowest temperature (See Section 4.7). The solar array has been sized to provide sufficient power to the CubeSat subsystems without the need for a battery even at apoapsis, though the Li-Ion battery will be able to provide additional power if necessary (See Section 4.5).

Upon nearing apoapsis, the CubeSat will once again use its ACDS system to determine the direction of the Zodi Cloud and orient itself accordingly (See Section 4.6). To ensure the entire Zodi Cloud is imaged, the CubeSat's optical payload (See Section 4.1) will once again capture the full horizon in 232 images. This imaging process will take 9.67 days. Like at periapsis, each image will be stored in the CubeSat's on-board harddrive and redundantly copied to protect the data from cosmic radiation bit flips (See Section 4.4).

After capturing and storing another full horizon of images, the Zodi CubeSat will once again reenter standby mode and recharge its Li-Ion battery if necessary. It will take approximately 104.2983 days for the CubeSat to reach its altitude of closest approach with Earth, where it can begin transmission of its collected image data.

### Event 6: Data Transmission on Earth Flyby

After collecting its final horizon of Zodi Cloud images at apoapsis, the CubeSat will reintercept Earth's orbit approximately one year after inserting into its final orbit. The CubeSat will pass Earth at an altitude of closest approach of 8371 km (See Listing 1). This distance represents the best time for our CubeSat to transmit its data. Using either the Near-Earth Network (NEN) or DSN (See Link Budget in Appendix C), the CubeSat will transmit all of its collected data using an X-Band Transmitter and omni-directional antenna (See Section 4.3). If transmitting to the DSN, this transmission will take 68 seconds. If transmitting to the NEN, this transmission will take 1.93 hours.

After transmitting all of its data, the primary mission of the Zodi CubeSat will be over. After this point, additional software could be uploaded to the CubeSat to have it pursue additional imaging missions suitable to its high inclination and hardware. Alternatively, the CubeSat could be left to autonomously collect and transmit additional image data until its systems fail. In either case, the completion of this event marks the successful completion of the Zodi CubeSat zodiacal light imaging mission.

## 3 Extracting Orbital Parameters

### 3.1 Early Calculations

As stated previously, the working trajectory for our Zodi CubeSat is based on calculations laid out by Gabrial Soto in his paper [1]. However, prior to the receiving the ZODIstatesAfter-FinalFlyby.mat file from Gabriel Soto, rough calculations were performed to determine the CubeSat's approximate final orbital parameters for initial sizing estimates. These approximate orbital parameters were determined using only the orbital height above the ecliptic at apoapsis, the orbital height below the ecliptic at periapsis, and the trajectory plot given in Gabriel Soto's paper [1].

Based on the knowledge that the CubeSat's final orbit has an orbital period ratio with respect to earth of 1, the orbital period of the CubeSat was determined to be approximately 365 days (or 3.154e7 seconds). From this orbital period, the approximate mean motion, n, and approximate semi-major axis, a, were calculated:

$$n \approx \frac{2\pi}{P_{Earth}} = \frac{2\pi}{1 \ year} = \frac{2\pi}{3.154e7 \ sec} = 1.992e - 7 \ rad/s$$
$$a \approx \sqrt[3]{\frac{\mu_{sun}}{n^2}} = \sqrt[3]{\frac{1.32712440041e20 \ m^3/s^2}{(1.992e - 7 \ rad/s)^2}} = 1.4954e11 \ m$$

Looking at Figure 8 in Gabriel Soto's paper [1], it was determined that the X and Y values of the CubeSat's periapsis are approximately equal to the X and Y values of Venus' orbital radius,  $\approx 1.082e11$  m from the Sun. According to Gabriel Soto's calculations, shown in the rightmost column of Table 2 of Gabriel Soto's paper [1], the periapsis of the CubeSat's orbit is approximately 0.1283 AU (1.9193e10 m) below the ecliptic. Using these values and Pythagoras' theorem, approximate values for the orbital radius at periapsis,  $r_p$ , and inclination, *i*, of our CubeSat were calculated:

$$r_p \approx \sqrt{(r_{venus})^2 + (z_{peri})^2} = \sqrt{(1.082e11 \ m)^2 + (1.9193e10 \ m)^2} = 1.09889e11 \ m$$
$$i \approx \arctan \frac{z_{peri}}{r_{venus}} = \arctan \frac{1.9193e10 \ m}{1.082e11 \ m} = 10.05875^{\circ}$$

With these values, approximate values for the eccentricity, e, the radius at apoapsis,  $r_a$ , the semi-parameter, p, the velocity at periapsis,  $v_p$ , and the velocity at apoapsis,  $v_a$ , were

00000 11

calculated:

$$e \approx 1 - \frac{r_p}{a} = 1 - \frac{1.09889e^{11} m}{1.4954e^{11} m} = 1 - 0.2651 = 0.26515$$

$$r_a \approx a(1+e) = (1.4954e^{11} m)(1+0.26515) = 1.8919e^{11} m$$

$$p \approx a(1-e^2) = (1.4954e^{11} m)(1-0.26515^2) = 1.39e^{11} m$$

$$v_p \approx \sqrt{\frac{\mu_{sun}}{r_p}(1-e)} = \sqrt{\frac{1.32712440041e^{20} m^3/s^2}{1.09889e^{11} m}}(1-0.026515)} = 39088.564 m/s$$

$$v_a \approx \sqrt{\frac{\mu_{sun}}{r_p}}(1+e) = \sqrt{\frac{1.32712440041e^{20} m^3/s^2}{1.09889e^{11} m}}(1+0.026515)} = 22704.19341 m/s$$

These values provided us with working orbital parameter data until more exact parameters could be extracted from the .mat file provided by Gabriel Soto. It is worth noting that the maximum percent error between any rough calculation and its more exact .mat counterpart was only 2.93%. After obtaining the .mat file from Gabriel Soto, the full orbital data was extracted and these approximate values were no longer necessary. All data and calculations presented in this paper, where applicable, use the more exact orbital parameter values extracted from ZODIstatesAfterFinalFlyby.mat as described in Section 3.2.

### 3.2 Extracting Exact Parameters from ZODIStatesAfterInitialFlyby.mat

The ZODIstatesAfterFinalFlyby.mat MATLAB file contains the X, Y, and Z coordinates of the CubeSat's position and velocity vectors relative to the sun for its proposed final orbit, propagated across 30000 timesteps. ZODIstatesAfterFinalFlyby.mat simulates the orbit of our CubeSat for 3 complete orbits across 800.216 days with 30000 timesteps of 2304.699 seconds (38.4117 minutes) each. The orbital trajectory of the CubeSat after its inclination change but prior to its first Earth transmission window is shown below in Figure 3 (3D View) and Figure 4 (Top-Down View):

Figure 3: A 3D plot of the orbital trajectory of the Zodi CubeSat after completing its inclination change but before the first Earth transmission window. The position of the sun is shown as a red 'X'.

Figure 4: A top-down plot of the orbital trajectory of the Zodi CubeSat after completing its inclination change but before the first Earth transmission window. The position of the sun is shown as a red 'X'.

In addition to determining the time of simulation and plotting the trajectory, ZODItrajectory.m also extracts more precise orbital parameters for this simulated final orbit. The orbital elements and more are contained in the printed output from the "Trajectory & Orbit Info" section of the ZODItrajectory.m script, shown below in Listing 1. All calculations presented in this paper, where appropriate, use the orbital elements listed below in Listing 1:

The Zodi CubeSat's camera is comprised of an ADCS-2120 monochrome image sensor [2] at the center of a 1U Cassegrain optical telescope setup, modeled after the STARE pathfinder's optical payload [3]. The CubeSat's camera represents the scientific payload for this zodiacal light imaging mission. Because of the importance of this subsystem, a trade study was performed comparing numerous image sensors. The parameters of the most promising image sensors that were analyzed are shown above in Table 3. Using these parameters a Pugh matrix was assembled, shown below in Table 4, and from this the ADCS-2120 Monochrome image sensor was selected.

Table 4: Pugh matrix comparing the multiple image sensors analyzed for use on the Zodi CubeSat. The UI-1462LE-C is used as the reference for this Pugh matrix. Using this Pugh matrix, the ADCS-2120 Monochrome image sensor was selected (highlighted in table).

The ADCS-2120 Monochrome image sensor was selected over the OV7620 due to the ADCS-2120's flight heritage aboard the CANX-1 satellite [4]. The monochrome version of the ADCS-2120 was selected to preserve the pure scientific imaging data that a color image sensor would lose when filtering the captured photons into colored pixels.

The MATLAB script ZODIphototime.m (See Appendix D.3) calculates the time it will take the ADCS-2120 to capture a single image of the zodiacal cloud, as described in Stark et. al. [5], assuming a read time of 1000s and a 10cm aperture. ZODIphototime.m calculates that it will take the ADCS-2120 sensor 2665.7099 seconds (44.4285 minutes) to capture a single image of the zodiacal cloud. For sizing and safety purposes, we round this value up and assume the ADCS-2120 sensor will take 1 hour to capture a single image. As can be seen in Table 3, it will take the ADCS-2120 sensor 232 images to capture a full horizon (incorporating a safety factor of 2). At one hour per image, this translates to 835575 seconds (9.67 days) per full horizon of images at both periapsis and apoapsis. Taking 9.67 days to image the zodiacal cloud at periapsis and apoapsis is well within the realm of feasibility for this mission. For this reason, the ADCS-2120 Monochrome image sensor [2] was determined to be a suitable image sensor for the Zodi CubeSat mission. The ADCS-2120 monochrome image sensor would be able to image the zodiacal cloud at both periapsis and apoapsis with high resolution, in a reasonable period of time, and with a low enough impact to the overall size of the CubeSat to ensure it remains below 6U, thereby meeting all the requirements of this mission's scientific payload.

### 4.1.2 Recommendations for Future Work

Future work on the optical payload will involve a more detailed design of the telescope optical system. We currently size our optical payload by comparing it to the 1U Cassegrain optical telescope system used by the STARE pathfinder mission [3], but this remains a rough estimate until it can be confirmed that the same optical setup will work for our specific mission. At this time, there does not appear to be any reason why the optical system used by STARE could not be adapted to our system, but confirmation remains a necessary step.

Though the values used were suitable for sizing and feasibility analysis, a number of the camera parameters could use further refinement before implementation. The focal length and Mb per photo represent two areas where additional refinement would be particularly helpful.

and the family of the state of

### 4.2 Propulsion Subsystem

### 4.2.1 Analysis

A trade study was performed on various propulsion systems in an attempt to optimize thruster volume, specific impulse, and force, in that order. Because of the single  $\Delta v$  requirement of 37.21m/s, the sizable time period until data collection after deployment, and an absence of a station-keeping requirement, the Busek Electrospray Thruster (BET) 100 $\mu$ N variant (BET-100 $\mu$ N) [12] and 1mN variant (BET-1mN) [13] were selected for further analysis. These electrospray thrusters were chosen for their low dry volume, high specific impulse, high efficiency, and subsequently low fuel requirement.

Electrospray propulsion is a form of electric propulsion that produces thrust via electrostatic acceleration of droplets of charged ionic liquid (such as the 1-Ethyl-3-Methylimidazolium ionic fluid used in our propellant calculations in Appendix A). In addition to creating an electric field to accelerate this plume of charged liquid, Busek's Propellantless Field Emission Cathodes [14] also provide carbon nanotube sites for the charged plume to be neutralized, preventing a charge from being induced on the CubeSat's exterior. The primary benefits of electrospray propulsion are that it features a high specific impulse, high thrust density, and high efficiency at the cost of lower total thrust and higher power requirements when compared to chemical propulsion.

Busek's electrospray thrusters, cathodes, and valves also have the added benefit of flight heritage aboard the NASA ST-7 ESA LISA Pathfinder [15]. According to Busek's website, the "LISA Pathfinder launched from Kourou in December of 2015 and all electrospray thruster units were successfully commissions[sic] in January 2016, after having been stored, fully fueled for nearly eight years. After reaching Earth-Sun Lagrange Point 1, the thrusters accumulated an average of 2,500 hours operation each and met 100% of mission goals"[16]. For this reason, electrospray thrusters were determined to be a suitably reliable technology for use aboard our CubeSat.

The BET-100 $\mu$ N electrospray thruster features a nominal specific impulse of 2300s, a volume 1/3 U (including electronics), a dry mass of 0.329kg, and a nominal thrust of 100 $\mu$ N. The BET-100 $\mu$ N requires 5.5W of power and an input voltage of 5.0-8.6VDC while in operation. These features of the BET-100 $\mu$ N and others are summarized below in Table 6:

BET-100µN Electrospray Thruster				
System Power	5.5 W			
Input Voltage	5.0-8.6 VDC			
Interface	RS-422, RS-485			
Propellant	Ionic Liquid			
Cathode	Carbon Nanotube Field Emission			
Thrust	100 μN nominal			
Specific Impulse	2,300 sec nominal			
Delta-V	85m/s for 4kg CubeSat			
Total Impulse	338 N-s (10mL propellant)			
Dimensions	9cm x 9cm x 4cm			
System Volume (including	1/3 U			
electronics)				
System Dry Mass	0.329kg			

Table 6: BET-100 $\mu$ N electrospray thruster product features. Pulled from Busek's BET-100 $\mu$ N Datasheet [12].

The BET-1mN electrospray thruster features a nominal specific impulse of 800s, a volume 1 U (including electronics), a dry mass of 1.15kg, and a nominal thrust of 0.7mN. The BET-1mN requires 15W of power and an input voltage of 9-12.6VDC while in operation. These features of the BET-1mN and others are summarized below in Table 7:

BET-1mN Electrospray Thruster			
System Power	15 W		
Input Voltage	9-12.6 VDC		
Interface	UART		
Propellant	Ionic Liquid		
Cathode	Carbon Nanotube Field Emission		
Thrust	0.7mN nominal		
Specific Impulse	800 sec nominal		
Delta-V	151m/s for 4kg CubeSat		
Total Impulse	605 N-s (10mL propellant)		
Dimensions	9cm x 9cm x 4cm		
System Volume (including	1 U		
electronics)			
System Dry Mass	1.15kg		

Table 7: BET-1mN electrospray thruster product features. Pulled from Busek's BET-1mN Datasheet [13].

As can be seen in Table 6 and Table 7, the BET-100 $\mu$ N thruster features a much higher specific impulse of 2300s compared to the BET-1mN's 800s specific impulse, a lower system volume of 1/3U compared to the BET-1mN's 1U system volume, but also a much lower nominal thrust of 0.1mN compared to the BET-1mN's 0.7mN nominal thrust. For our 4U CubeSat, the BET-100 $\mu$ N thruster would be more than capable of delivering the required 37.21m/s  $\Delta v$ burn, but its lower thrust would require a much longer time period to execute the burn. Using the mass of our CubeSat (See Appendix A) with the propulsion system mass swapped out according to each thruster, the time required for each thruster to execute the 37.21m/s  $\Delta v$  burn (assuming constant thrust) was calculated like so:

$$F_{thrust} = m \frac{\Delta v}{\Delta t}$$

$$\Delta t_{BET-100\mu N} = m \frac{\Delta v}{F_{BET-100\mu N}} = (4.39889 \ kg) \frac{37.21 \ m/s}{0.0001 \ kg \ m/s^2} = 1636826.969 \ s = 18.9 \ days$$

$$\Delta t_{BET-1mN} = m \frac{\Delta v}{F_{BET-1mN}} = (5.225744 \ kg) \frac{37.21 \ m/s}{0.0007 \ kg \ m/s^2} = 277785.6203 \ s = 3.2 \ days$$

According to these calculations, to execute a 37.21m/s  $\Delta v$  burn, the BET-100 $\mu$ N would require 18.9 days, whereas the BET-1mN would require 3.2 days.

Given the proper trajectory planning, the BET-100 $\mu$ N thruster, with its required burn time of 18.9 days, could feasibly perform the required inclination change maneuver for our CubeSat. This said, the calculated  $\Delta v$  burn of 37.21m/s assumed a single, impulsive burn, and the actual  $\Delta v$  requirement will increase as it approaches periapsis. Spending 18.9 days implementing an inclination change burn, while possible, would require much more complex simulation and control than has currently been performed in order to ensure our CubeSat still ends up in its desired final orbit. How this additional complexity and control will affect our Power and ACDS subsystems is unknown at this time and remains an area for future study.

The BET-1mN would be able to execute the calculated  $\Delta v$  burn of 37.21m/s in just 3.2 days. Once again, because the calculated  $\Delta v$  burn of 37.21m/s assumed a single, impulsive burn, the actual  $\Delta v$  requirement will be slightly higher, but less-so than in the BET-100 $\mu$ N case as the BET-1mN will be able to complete the burn farther from periapsis. Additionally, the higher thrust of the BET-1mN will provide greater contingency for our current trajectory and allow for greater versatility in selecting new trajectories should our current become unavailable.

Because it is, at the time of this writing, unclear as to whether the potential benefits of the BET-100 $\mu$ N's lower volume and mass would outweigh the potential additional power requirements and risk of failure associated with a 18.9 day continuous burn, the **BET-1mN Electrospray Thruster** has been chosen as the Zodi CubeSat's propulsion system. The BET-1mN Electrospray Thruster [13] will be able to execute the required inclination change burn of  $\approx 37.21$ m/s, in a reasonable period of time (3.2 days), and with an acceptable impact on the overall size of our CubeSat (1U thruster module, 0.02U propellant; See Appendix A), thereby meeting all the requirements of our propulsion subsystem.

### 4.2.2 Recommendations for Future Work

Additional orbital dynamics analysis should be performed with the BET-1mN incorporated into the design, and it is the opinion of this author that additional orbital dynamics analysis should also be performed on the BET-100 $\mu$ N until the additional requirements its longer burn time imposes are better understood. One goal of this orbital dynamics analysis will be to get a more accurate value for the required  $\Delta v$  maneuver for both the BET-1mN and the BET-100 $\mu$ N assuming a **continuous** burn, thereby allowing for their respective burn times and required propellant mass to be updated accordingly. This analysis will also provide insight into the ACDS requirements for executing both the BET-1mN burn and the BET-100 $\mu$ N burn in such a way as to still achieve our desired final orbit, guiding the ACDS team in their feedback controller designs and helping to determine the overall feasibility of the BET-100 $\mu$ N thruster.

If this analysis determines that utilizing the BET-100 $\mu$ N will require drastic changes to the CubeSat design, impose a much higher risk than the BET-1mN, and/or if continued analysis on the BET-100 $\mu$ N would lead to unacceptable delays in the future progression of the project, then further analysis on the BET-100 $\mu$ N should be scrapped and all analysis moving forward should only include the BET-1mN. But if analysis determines that the benefit of the lower volume and mass of the BET-100 $\mu$ N outweigh its added complexity and risk, then it may be worth switching the propulsion system over to the BET-100 $\mu$ N, at the project team's discretion.

### 4.3 Communications Subsystem

Requirement ID	Communications Subsystem Requirements	Mapping to
		System-Level
		Requirements
COM-REQ 1	The communications system must transmit two full horizons	REQ 7
	worth of Zodiacal Dust images to Earth before end of life.	
COM-REQ 2	The size of the communications system must be small enough to	REQ 1
	ensure that it does not put the total size of the CubeSat above 6U	

Table 8: Communications Subsystem Requirements for the Zodi CubeSat Mission

### 4.3.1 Analysis

After collecting its final horizon of images at apoapsis, the CubeSat will pass Earth at an altitude of closest approach of 8731 km. This transmission window, and during its Earth gravity-assist represent the two best opportunities to communicate with the CubeSat. Communication via the DSN outside of these two events may be possible if emergency software updates are necessary, but obtaining time on the DSN for this purpose cannot be counted on. For this reason, all communication between Earth and the CubeSat is assumed to be made at this altitude of closest approach of 8371 km.

The CubeSat will transmit in the X-Band at 8.45GHz. The X-Band was chosen due to its high datarate capabilities and legacy for deep-space science missions. Based on the CPUT XTX X-Band Transmitter [17] and Alaris OMNI-A0150 High Gain X-Band Omni-directional Antenna [18], a link budget was assembled for both the Deep Space Network (DSN) and Near Earth Network (NEN) as potential ground receivers (See Appendix C). Based on the CPUT Transmitter datasheet, a RF power of 2W (3dBW) was chosen and the datarate was not allowed to exceed 50Mbps, keeping within the CPUT Transmitter's limits. Similarly, based on the OMNI-A0150 Antenna datasheet, an antenna gain of 4dBi was chosen based on the OMNI-A0150's limits. At this transmission frequency of 8.45GHz and distance of 8731km, the worst-case total losses were assumed to be 194.647681dB for the DSN and 197.182681dB for the NEN (See Appendix C). Our transmitter will use QPSK modulation with a 9/10 code rate, resulting in a required signal-to-noise ratio  $\left(\frac{E_b}{N_0}\right)$  of 3.89dB.

In order to account for uncertainty in some assumed values, a link margin of at least 3dB was chosen. For the DSN, a 40 Mbps datarate would result in a predicted  $\frac{E_b}{N_0}$  of 16.242dB, a link margin of 12.352dB, and allow two horizons worth of Zodi images ( $\approx 2720$  Mb with data redundancy of 2; See Section 4.4) to be transmitted in 68 seconds. For the NEN, a 0.392430

Mbps datarate would result in a predicted  $\frac{E_b}{N_0}$  of 6.89dB, a link margin of 3dBm and allow two horizons worth of Zodi images ( $\approx 2720$  Mb; See Section 4.4) to be transmitted in 6931.17 seconds (1.93 hours).

Of our two analyzed ground stations (the DSN and NEN), the NEN is far more likely to be our final ground station, due to the high demand and cost of the DSN. The 1.93 hour transmission time that would result from the 0.392430 Mbps transmission datarate to the NEN is perfectly feasible, and could be further improved if link margins below 3dB are allowed. Additionally, the high 16.242dB link margin that would result from using the DSN as a ground station suggests that transmission could begin at distances much farther than the 8371km altitude of closest approach if the DSN is used. Both of these results prove the feasibility of using an X-Band transmitter and omni-directional antenna like the CPUT XTX Transmitter and Alaris OMNI-A0150 for our Zodi CubeSat. The CPUT XTX Transmitter [17] and Alaris OMNI-A0150 Antenna [18] would be able to transmit all scientific data to the NEN in a reasonable period of time (1.93 hours), retain a 3dB link margin as they do so, and with an acceptable impact on the overall size of our CubeSat (0.092U transmitter, 0.046U antenna; See Appendix A), thereby meeting all the requirements of our communications subsystem.

#### **Recommendations for Future Work** 4.3.2

Though the values used were suitable for sizing and feasibility analysis, where possible the link budget should be further refined. More accurate values for losses as well as specific target ground stations (rather than just sizing for the worst ground station in each network) would improve our link budget and likely our maximum datarate by extension. A better understanding of the specific losses and ground stations that our CubeSat will encounter will allow us to confidently lower our required link margin and raise our maximum datarate.

The costs and availabilities of both the DSN and NEN ground stations should be looked into as the project progresses. From this, the final feasibility of using the DSN as a primary or emergency ground station can be determined. Additional analysis should be performed incorporating the relative positions of the Earth and CubeSat to determine available contact windows using the DSN in the event an emergency software update is necessary.

Additional work should also be done to assemble an uplink link budget to complement the downlink link budget provided in Appendix C. The downlink link budget was assembled using the CPUT XTX transmitter as a reference, so further research should also be done to find a similar or superior transceiver should the CPUT XTX be incapable of receiving data.

#### Command & Data Handling Subsystem 4.4

Table 9: C&DH Subsystem Requirements for the Zodi CubeSat Mission					
Requirement ID	Command & Data Handling Subsystem Requirements	Mapping to System-Level Requirements			
CDH-REQ 1	The C&DH system will ensure the CubeSat accomplishes all mission goals autonomously and without computational error due to cosmic radiation.	REQ 2 REQ 5			
CDH-REQ 2	The C&DH system will ensure that all collected data is stored and protected from corruption due to cosmic radiation.	REQ 6			
CDH-REQ 3	The size of the C&DH system must be small enough to ensure that it does not put the total size of the CubeSat above 6U.	REQ 1			

### 4.4.1 Analysis

Our CubeSat will use triple modular redundancy (TMR) to ensure the mission is executed autonomously and without faults once it has been deployed. TMR is the process by which three identical systems run the same identical processes and execute a final command based on majority consensus, thereby protecting the system logic from bit flip errors caused by cosmic radiation. This TMR system will be comprised of three micro-controllers. For sizing we used three Raspberry Pi Model 3B+'s as a reference. This Raspberry Pi TMR would require only 3.6W to operate [19].

The C&DH system will also be responsible for ensuring all the collected scientific data is stored without error until it can be transmitted back to Earth. As mentioned previously, a horizon of photos would be approximately 680Mb of data in their uncompressed form (See Section 4.1). Because our CubeSat will collect images from both periapsis and apoapsis, raw image data will take up 1360 Mb of data storage. To protect this data against bit flip faults caused by cosmic radiation, a data redundancy of 2 will be applied (system will store 2 copies of all scientific data), resulting in a total 2720 Mb of image data. A small, 5 Gb solid-state harddrive would be able to feasibly store this collected data as well as any algorithms the CubeSat will need to operate autonomously.

Using this configuration, the C&DH subsystem will feasibly be able to ensure the Zodi CubeSat can operate autonomously, store all collected scientific data without errors, and have minimal impact on the overall size of our CubeSat, thereby meeting all the requirements of the C&DH system.

### 4.4.2 Recommendations for Future Work

The primary focus of future C&DH work will involve the design of the CubeSat's autonomous operation algorithms. These algorithms are **mission critical**, as the CubeSat will need to work autonomously and reliably at the distances outside of communication range, where opportunities to diagnose and fix software problems will be extremely limited or potentially nonexistent. Additional work is to be done on the design and implementation of both the hardware and software of the TMR system. Additional research into potential micro-controllers should also be performed to ensure they will be able to operate at the temperatures that our CubeSat will be exposed to (See Section 4.7).

### 4.5 Power Subsystem

Requirement ID	Power Subsystem Requirements	Mapping to
		System-Level
		Requirements
PWR-REQ 1	The power subsystem will ensure that sufficient power is	REQ 5
	provided to all necessary CubeSat hardware until end of life in	REQ 7
	order to facilitate the completion of the mission.	
PWR-REQ 2	The size of the power subsystem must be small enough to ensure	REQ 1
	that it does not put the total size of the CubeSat above 6U.	

Table 10: Power Subsystem Requirements for the Zodi CubeSat Mission

### 4.5.1 Solar Array Analysis

The CubeSat will feature body-mounted and deployable Triple-Junction GaAs solar arrays using the AzurSpace Triple-Junction GaAs solar cell [20] as a reference. This solar array will provide a total sun-incident surface area of  $1200cm^2$  ( $0.12m^2$ ) and will be able to provide power to all subsystems even when operating at maximum power. The sizing derivation for this solar array is as follows.

Based on the maximum power requirements from our power budget (See Appendix B), the CubeSat will require 25W while executing its inclination change, 10.2W while imaging the zodiacal cloud, 10W while in transit/standby between mission events, and 25W while transmitting data to Earth. For sizing purposes, these values assume the overestimated case of all utilized hardware operating at its maximum wattage while in use.

The "Solar Panel Power Generation" section of ZODItrajectory.m (See Appendix D.1) derives the end-of-life (EOL) power that would be generated by  $1200cm^2$  worth of Silicon, GaAs, and Triple-Junction GaAs solar cells between orbit insertion/periapsis, periapsis/apoapsis, and apoapsis/Earth-transmission. These EOL power generation values are generated assuming an incidence angle of 9.7725° (inclination of orbit), a beginning-of-life (BOL) inherent degradation of 0.7225 (that is, the degradation will cause the cell to generate 72.25% of intended power), a Triple-Junction GaAs cell efficiency of 0.28, a GaAs cell efficiency of 0.185, and a Silicon cell efficiency of 0.148.

EOL degradation due to radiation is estimated according to the 1MeV particle fluences estimated by ZODIpanelDegradation.m (See Appendix D.2), using the NASA GaAs Radiation Handbook [21] as a guide. ZODIpanelDegradation.m makes the rough assumption that the CubeSat will experience 3 worst-case solar events at every energy range based on historically recorded maximum-energy solar event data. This is likely a gross overestimation of the actual solar fluences the CubeSat will experience. ZODIpanelDegradation.m further overestimates the damage that will be caused by solar events by taking degradation values for solar cells with no cover glass (the Zodi CubeSat solar array will likely have cover glass). By sizing our panels according to these overestimations, we hope to protect our solar array from errant high-energy solar events as well as incorporate temperature degradation due to the high temperatures the panels will reach at periapsis (See Section 4.7). Using this model, ZODIpanelDegradation.m estimates a total solar 1MeV fluence of 2.383e15 particles per  $cm^2$  over the lifetime of the CubeSat. This maps to a power degradation of 0.85 according to the AzurSpace Triple-Junction GaAs Solar Cell Datasheet [20] and a power degradation of 0.85 according to the Spectrolab Ultra-Triple-Junction GaAs Cell Datasheet [22], but due to the imprecise nature of ZODIpanelDegredation.m, an EOL degradation value of 0.80 was chosen for extra safety.

The absolute worst-case scenario would be if a high-energy solar event occurs while the CubeSat is at periapsis. This is modeled in ZODIpanelDegradation.m as 1 worst-case event at every energy level occurring when the CubeSat is closest to the sun at periapsis. If this occurs, the CubeSat will be subjected to 1.211e15 particles per  $cm^2$  per minute. This will not only kill the solar panels, but likely any electronics within the CubeSat. Due to the CubeSat's small size, there is unfortunately little that can be done to shield the craft from this event should it occur. Luckily, solar events of this magnitude only occur very infrequently during solar maximum, so ensuring the CubeSat will reach periapsis outside of solar maximum will reduce this risk astronomically. Even in the event where launching outside of solar maximum is impossible, these high-energy solar events are significantly rare, so the probability of one occurring while

the CubeSat is at periapsis is extremely low. Ultimately, because of the unpredictable nature of when solar events will occur, the lack of methods available to protect a CubeSat from it, and the relative low cost of a CubeSat, it is the opinion of this author that future Zodi mission designers keep this worst-case scenario in mind, but not let it drive mission-critical decisions.

With BOL and EOL degradation values obtained, ZODItrajectory.m calculates the solar flux incident on the CubeSat at each point in its orbit, and from this calculates the power generated by each type of solar array assuming EOL power generation throughout. In the "Battery & Solar Panel Sizing" section of ZODItrajectory.m, the script goes on to determine the minimum number of 10x10cm panels necessary to make batteries unnecessary, assuming no eclipse. Inspecting the trajectory indicates that the CubeSat will be positioned between the Earth and Sun during transmission, and therefore will not be eclipsed by the Earth during this time, thus this is a reasonable assumption. These values are output by the script and shown below in Listing 2:

```
Power Used In Transit (Standby): 10 W
   Number of 10x10cm Solar Panels: 12
   Power Generated In Transit:
      Power Generated Before Periapsis:
      Triple Junc GaAs: 167822634.7321 W*s
      GaAs: 90817937.716 W*s
      Si: 60826634.6677 W*s
      Power Generated Between Periapsis and Apoapsis:
      Triple Junc GaAs: 252738384.9306 W*s
      GaAs: 116286128.669 W*s
      Si: 63141565.704 W*s
      Power Generated Between Apoapsis and Earth Transmission:
      Triple Junc GaAs: 84747100.864 W*s
      GaAs: 25388039.9868 W*s
      Si: 2269247.8557 W*s
   Minimum Number of 10x10cm (TripleGaAs) Solar Panels to Make Batteries Unnecessary: 10.1339
20
   Minimum Number of 10x10cm (GaAs) Solar Panels to Make Batteries Unnecessary: 15.3379
   Minimum Number of 10x10cm (Si) Solar Panels to Make Batteries Unnecessary: 19.1723
   Number of 10x10cm Solar Panels: 12
    Minimum LiIon Battery Volume: -7.4489e-05 m<sup>3</sup> = -0.074489U (assuming TripleGaAs Solar Cells
        \rightarrow)
    Minimum NiCd Battery Volume: -0.0001243 m<sup>3</sup> = -0.1243U (assuming TripleGaAs Solar Cells)
    Minimum NiH2 Battery Volume: -0.00031577 m<sup>3</sup> = -0.31577U (assuming TripleGaAs Solar Cells)
```

Listing 2: Output of the "Solar Panel Power Generation" and "Battery & Solar Panel Sizing" sections of the ZODItrajectory.m MATLAB script. Negative "Minimum Battery Volume" values indicate that the solar array would be able to provide power balance without a battery. See full ZODItrajectory.m script in Appendix D.1

The script also plots the power that would be generated by each type of  $1200cm^2$  solar array as a function of time, as shown in Figure 5:

Figure 5: Plot of power generated by a  $1200cm^2$  sun-incident Triple-Junction GaAs, GaAs, and Silicon type solar array. Plot generated by ZODItrajectory.m MATLAB script. See full ZODItrajectory.m script in Appendix D.1.

Thus it was determined that a  $1200cm^2$  Triple-Junction GaAs solar array would be able to provide power to the Zodi CubeSat at all mission stages, even with all hardware operating at maximum wattage. A battery would not be necessary to provide power to the system, but our power subsystem still features a 1/3U Li-Ion battery for safety purposes (See Section 4.5.2 for more details). Therefore, we have concluded that the Zodi CubeSat could feasibly operate with a combination of body-mounted and deployable solar arrays (See CAD model in Figure 1) made up of Triple-Junction GaAs cells like the **AzurSpace Triple-Junction GaAs Cell** [20]. This power subsystem would safely power the Zodi CubeSat for the duration of its mission and would not impact the overall size of the CubeSat such that it exceeds 6U (See Appendix A), thereby meeting all of its subsystem requirements.

### 4.5.2 Battery Sizing Analysis

The "Battery & Solar Panel Sizing" section of ZODItrajectory.m calculates the battery volume that would be required to provide power balance for a given solar array surface area. The script performs this analysis for Li-Ion, Ni-Cd, and Ni-H2 batteries. As mentioned previously in Section 4.5.1, the solar array of the Zodi CubeSat is sized such that the solar array alone will be able to provide power to all hardware at all stages in the mission. For safety, however, the CubeSat will contain a 1/3U Li-Ion battery. This battery will be able to act as a bridge between the solar arrays and the rest of the CubeSat hardware, provide power to the CubeSat hardware in the event of incomplete solar array deployment, provide power in the event of solar eclipse, and provide internal heating to the CubeSat at apoapsis. A fully charged 1/3U Li-Ion battery with a volumetric energy density of 250Wh/L would be able to provide 83.333 Wh of power. This would help cover some or even all of the power deficit caused by a partially-deployed solar array wing.

The only points at which our CubeSat's view of the sun may become eclipsed are during

its final Earth gravity-assist (eclipsed by the Earth) and possibly while it is transmitting its scientific data one year later (eclipsed by the moon). In the former case, the battery will be able to provide 8 hours of power while the CubeSat operates in standby (10W used in standby; See Appendix B), ensuring the CubeSat remains powered until it has passed the Earth. In the later case, the power requirement will be higher due to data transmission. Based on our link budget (See Appendix C), the longest required time to transmit all collected data would be approximately 1.93 hours. This means that, should the sun be eclipsed by the moon during transmission, a fully charged 1/3U Li-Ion battery would be able to provide 43.28 W for the duration of the transmission time. Considering that the CubeSat will require a maximum of 25W (See Appendix B) during transmission, the power provided by this Li-Ion battery would be more than enough even after factoring in a year's worth of degradation and duty-cycling.

For this reason, a 1/3 U Li-Ion battery would feasibly be able to provide power to the Zodi CubeSat even in the event of solar array deployment failure and/or a solar eclipse, thereby ensuring the CubeSat will remain powered in all stages of its mission. As an added bonus, the battery will generate heat and warm the interior of the CubeSat when it is at its coldest at apoapsis. For more thermal analysis concerning the battery, see Section 4.7.

### 4.5.3 Recommendations for Future Work

The power subsystem was sized using a number of overestimations to ensure it would be able to meet the requirements of the system. As a result of this, however, the power subsystem is likely larger than it actually needs to be in order to fully power all hardware on the CubeSat. Further refinement of the power subsystem should be done in the future in order to optimize the sizing of both the solar array and backup battery.

Though the values used were suitable for sizing and feasibility analysis, the solar array degradation calculations are particularly in need of refinement. As is, solar array degradation due to radiation is very roughly estimated assuming a specific number of events. A more proper and accurate method of quantifying the solar radiation that a spacecraft will encounter is to make a probabilistic model and select an expected total particle fluence value based on a probabilistic confidence value (of 90% for example). Additionally, solar array and battery degradation due to temperature need to be incorporated, especially for the deployable solar panels that will reach temperatures of up to 137.49°C at periapsis (See Section 4.7).

The current power subsystem design will require some level of regulated power bus due to the Li-Ion battery, but future analysis may allow for the system to be simplified to an unregulated configuration. Whether or not this simplification would actually add any value to the system, however, has not been meaningfully explored. In the case of a regulated power bus, this system will need to be designed in a way that makes the most sense for the Zodi CubeSat and its mission.

## 4.6 Attitude Control & Determination Subsystem

Requirement ID	Attitude Control & Determination Subsystem Requirements	Mapping to System-Level Requirements
ACDS-REQ 1	The ACDS system must be able to determine the CubeSat's position & orientation in space	REQ 2
ACDS-REQ 2	The ACDS system must be able to orient the CubeSat in any direction in 3D space.	REQ 2 REQ 3
ACDS-REQ 3	The ACDS system must be able to precisely point the CubeSat camera while it images the Zodiacal cloud	REQ 4
ACDS-REQ 4	The ACDS system must be able to counteract any sources of external torque without saturating its momentum wheels to ensure consistent attitude control until end of life.	REQ 5
ACDS-REQ 5	The size of the ACDS system must be small enough to ensure that it does not put the total size of the CubeSat above 6U.	REQ 1

Table 11: ACDS Subsystem Requirements for the Zodi CubeSat Mission

### 4.6.1 Attitude Determination Analysis

Orbital positioning will be provided by a sun sensor and star tracker due to the CubeSat's operation in deep space. An internal gyroscope will provide gyroscopic data to the Attitude Control system. If necessary, our scientific payload camera may be able to act as a star-tracker when not collecting scientific data by using an image-recognition algorithm, though a separate star tracker would be preferable to allow for orbital positioning determination during scientific data collection.

This setup would feasibly allow our Zodi CubeSat to determine its position on its orbital trajectory as well as its orientation in space, thereby meeting all the requirements of the attitude determination subsystem.

### 4.6.2 Attitude Control Analysis

The CubeSat will use a feedback controller hooked up to a 4-Wheel Reaction Wheel Assembly (RWA), using 4 Blue Canyon RWP050 Reaction Wheels [24] as a reference. The CubeSat will use cold-gas thrusters with RC134a propellant ( $I_{sp}=40$ ) to dump momentum and prevent reaction wheel saturation. This attitude control assembly was deemed suitable after sizing the sweeping angle, maximum anglular rate, and external torque imparted by solar radiation pressure.

Attitude control subsystem sizing was handled by the "Attitude Control System Sizing" section of ZODItrajectory.m (See Appendix D.1). This section of the script determines the maximum angular rate, max sweeping angle, and the change in momentum due to solar radiation pressure during image collection. Using this data, it determines the number of momentum dumps and mass of cold-gas fuel that will be required to dump all accumulated momentum in the CubeSat's lifetime.

The angular rate of the CubeSat will be highest operationally when the CubeSat needs to dwell on a single point. This occurs at both periapsis and apoapsis while the Camera is imaging the Zodi cloud. The required angular rate will be higher at periapsis due to the higher orbital velocity of the CubeSat, peaking when imaging precisely at periapsis. Using the ZODItrajectory.m script, it was determined that at periapsis the CubeSat will need to sweep 8.35067e-4 rad, resulting in a maximum angular rate of 3.62332e-7 rad/s. This is well within the capabilities of our proposed reaction wheel assembly. The script also determined that the CubeSat will need to sweep a total of 0.3 rad at periapsis and a total of 0.0991 rad at apoapsis while imaging the Zodi cloud.

After the CubeSat is deployed and leaves Earth's sphere of influence, until its next Earth flyby the only possible source of external torque will be solar radiation pressure. We make the assumption that while in transit, the CubeSat will be made to spin such that forces imparted by solar radiation pressure will cancel out. Using this assumption, the external torques for which our attitude control system must be sized will occur during photo collection at periapsis and apoapsis, where the CubeSat must stop spinning. We assume a worst-case scenario of a 10cm distance, D, between the CubeSat's center of mass and the center of incident solar radiation pressure. Because the exterior of our CubeSat is covered in solar arrays with an absorptivity of 0.91 [20], the reflectance of our CubeSat exterior is calculated to be  $R = \frac{1}{10^a} = \frac{1}{10^0.91} = 0.1230$ . Using this value, the instantaneous change in momentum due to solar radiation pressure was calculated like so:

$$\Delta M_{SRP} = \frac{\Phi_S(t)}{c} (A)(1+R)(D)(\Delta t) \cos \theta$$

Where  $\Phi_S(t)$  is the solar flux at time t, c is the speed of light (3e8 m/s), A is the surface area on which the sunlight will be incident, R is the reflectance, D is the distance between the center of mass and center of incident solar radiation pressure,  $\Delta t$  is the time over which the CubeSat will be exposed to these conditions, and  $\theta$  is the angle of the incident surface with respect to the incoming sunlight. For our calculations, the total change in momentum was calculated for the entire duration of image collection at periapsis and apoapsis taking  $D = 0.1 \ m$  (as mentioned previously),  $A = 0.12 \ m$  (the total area of solar panels incident to the sun), R = 0.1230 (as mentioned previously),  $\theta = 9.7723^{\circ}$  (inclination angle),  $\Delta t = 2304.699 \ s$  (the time between two datapoints), and  $\Phi_S(t)$  calculated for each datapoint during which images will be collected.

Using these parameters, it was determined that the total combined change in momentum that will occur at periapsis and apoapsis will be 0.1277 Nms. Taking the maximum momentum storage of each our 4 wheels to be 0.050 Nms (as described in the Blue Canyon RWP050 Datasheet [24]) and incorporating a safety factor of 1.2, this would result in our wheels reaching 76.62% saturation before end of life. This is well within acceptable limits. Nevertheless, to account for possible momentum imparted by the Earth and during deployment, a momentum dumping system was sized to remove the 0.1277 Nms that solar radiation pressure will impart.

As stated previously, our momentum dumping system consists of cold-gas thrusters using RC134a propellant. RC134a propellant has a specific impulse of 40 s. Assuming a 1 second burn time, incorporating a safety factor of 1.5 and assuming 10cm to be the largest moment arm distance for our thrusters, the total fuel required for our momentum dumping system was calculated as follows:

$$F_{MomentumDump} = \frac{\Delta M_{tot}}{(r_{moment\ arm})(t_{burn})} (X_{Safety}) = \frac{0.1277\ Nms}{(0.1\ m)(1\ s)} (1.5) = 1.916\ N$$
$$m_{RC134a} = (F_{MomentumDump}) \frac{N_{MomentumDumps}}{(g)(I_{sp})} = (1.916\ N) \frac{0.7662}{(9.80665\ m/s^2)(40\ s)} = 0.0037418\ kg$$

Where  $N_{MomentumDumps}$  is the number of times that the wheels must be completely dumped

of momentum (0.7662 because they only reach 76.62% saturation), and g is the gravitational constant (9.80665  $m/s^2$ ).

Using the atmospheric density of RC134a,  $4.25kg/m^3$ , a 5000 psia pressure tank, and Boyle's law, it was determined that this 0.0037418 kg of RC134a would translate to 2.588 $cm^3$  (0.00259 U) in volume, not counting its storage tank (See Mass-Vol Budget in Appendix A). This volume is more than acceptable and this cold-gas system would be able to dump all momentum imparted by solar radiation pressure, ensuring our system will be able to survive to end of life without wheel saturation. Based on this analysis, we can conclude that 4 reaction wheels similar to the **Blue Canyon RWP050** [24] and a cold-gas thruster array using RC134a fuel would provide feasible attitude control to our Zodi CubeSat. This attitude control system would be able to provide the necessary pointing slew rate, perturbation resistance, prevent wheel saturation, and do so with an acceptable impact on the overall size of the CubeSat, thereby meeting all attitude control subsystem requirements.

### 4.6.3 Recommendations for Future Work

The primary focus of future ACDS analysis will be the creation of a feedback controller for the ACDS system. To do this, a working inertia matrix will need to be determined based on the final design configuration of the CubeSat. Determining the actual position of the CubeSat's center of mass would be necessary for accurate attitude control and calculation refinement. Though the momentum values used were suitable for sizing and feasibility analysis, further refinement of the expected change in momentum would be beneficial, as would determining the required rotational dynamics during transit to ensure no net momentum is imparted.

Another area of future analysis would be the optimization of reaction wheel and momentum dumping thruster placement. Currently, the reaction wheel assembly is represented in the CAD model as a box (See Figure 2), and our CubeSat features far more momentum-dumping thrusters than are actually necessary, with 3 thrusters at each corner. The final positions and orientations of these reaction wheels and momentum-dumping thrusters should be optimized and finalized before the final assembly.

### 4.7 Thermal Analysis

### 4.7.1 Analysis

A finite element thermal analysis was performed in ANSYS for our CubeSat. Heat transfer via conduction across all components and radiation into/out of the exterior components was modeled. Internal radiation and internal heat sources were not modeled. The solar panels and camera lens on the exterior of the CubeSat were modeled as plexiglass with a thermal conductivity of 0.200 W/(mK) and an emissivity of 0.85, while all other components were modeled as an aluminum alloy with thermal conductivity according to Figure 6 as a function of temperature [25].

Figure 6: Thermal conductivity profile of Aluminum Alloy based on the results of Barucci et. al. [25] for temperatures below  $-100^{\circ}$ . For temperatures above  $-100^{\circ}$ , the standard "Aluminum Alloy" ANSYS profile was used.

A simulation was performed for the case of sunlight fully incident on one side of the CubeSat while at periapsis, representing the point at which our CubeSat will achieve its highest temperature. At periapsis, the CubeSat will be 108748530.4715 km from the sun and solar flux will be equal to  $2588.8W/m^2$ . The sun-facing side will be covered in solar cells with absorptivities of 0.91 [20]. To represent this, the sun-facing side was modeled as having an incident heat flux of  $2355.808W/m^2(=(0.91)*(2588.8W/m^2))$ . Applying these parameters in ANSYS to the CubeSat CAD Model in Figure 1 produced the following temperature distribution at periapsis, shown below in Figure 7:

Figure 7: Temperature distribution for our CubeSat at **periapsis**. Generated using ANSYS.

This temperature model indicates that at periapsis, the majority of the CubeSat will be between the temperature range of  $50-100^{\circ}$ C (with the exception of the deployed panels which will reach temperatures of 137.49°C).

A similar analysis was performed for the case of sunlight fully incident on one side of the CubeSat while at apoapsis, representing the point at which our CubeSat will achieve its lowest temperature. At apoapsis, the CubeSat will be 190397164.4198 km from the sun and solar flux will be equal to  $844.556W/m^2$ . Like before, the sun-facing side will be covered in solar cells with absorptivities of 0.91 [20]. To represent this, the sun-facing side was modeled as having an incident heat flux of  $768.55W/m^2(=(0.91)*(844.556W/m^2))$ . Applying these parameters in ANSYS to the CubeSat CAD Model in Figure 1 produced the following temperature distribution at apoapsis, shown below in Figure 8:

Figure 8: Temperature distribution for our CubeSat at **apoapsis**. Generated using ANSYS.

This temperature model indicates that at apoapsis, the majority of the CubeSat will be between the temperature range of  $-30-0^{\circ}$ C (with the exception of the deployed panels which will reach temperatures of  $30.365^{\circ}$ C).

A significant area of interest in this analysis is the temperature of the battery. Our CubeSat uses a Lithium Ion battery, which is sensitive to extreme temperatures. A typical Li-Ion battery is designed to safely charge in the  $0-45^{\circ}$ C temperature range and discharge in the  $-20-60^{\circ}$ C temperature range. Certain specialty Li-Ion batteries do exist that can safely operate outside of this range by a factor of  $\pm (5-10)^{\circ}$ C. A temperature probe was placed on the battery in both of our ANSYS models to determine the average steady-state temperature of our battery in the lowest and highest temperature cases (apoapsis and periapsis).

At periapsis, our battery reached a steady-state average temperature of approximately 60°C, as shown in Figure 9. This is towards the upper limit of the Li-Ion maximum discharge range, but still within feasible limits for a lithium ion battery with higher temperature tolerances. Charging while at periapsis will be unnecessary, as at this distance the solar array alone will be enough to supply power to all subsystems. Because of this, being outside the charging temperature tolerance should not be an issue. In the unlikely event that the Li-Ion battery must discharge to supply some additional power at periapsis, a lithium-ion battery with a slightly higher temperature tolerance will be able to handle this situation without incident. Incorporating internal radiation and internal temperature sources will likely change this resulting

temperature, so further analysis is necessary, but with proper power regulation this should not affect the battery temperature at periapsis by more than a few degrees.

Figure 9: Transient temperature of battery over the course of one day at **periapsis**. The initial jump seen in the plot is due to the model adjusting from the arbitrary initial temperature of  $22^{\circ}$ C. The section of the plot where the temperature levels out represents the steady-state temperature of approximately  $60^{\circ}$ C. Generated using ANSYS.

At apoapsis, our battery reached a steady-state average temperature of approximately -20°C, as shown in Figure 10. This is below the minimum charging temperature for Li-Ion batteries but above the minimum discharge temperature. In the case of apoapsis, incorporating internal radiation and internal temperature sources into our model will have a much greater effect on our system. The heat generated by the battery alone will likely raise the battery temperature by several degrees, potentially putting it above the minimum charging temperature. The use of lithium-ion batteries with a lower temperature tolerance would further assist in getting the temperature of the battery into the charge range. Regardless of whether or not the battery will achieve an effective charging temperature, however, the solar panels were sized to be able to provide enough power to all subsystems even at apoapsis. Because of this, at the only potential need for the battery at apoapsis would be discharging to supply power, which it is already within the temperature range to do.

Figure 10: Transient temperature of battery over the course of one day at **apoapsis**. The initial jump seen in the plot is due to the model adjusting from the arbitrary initial temperature of  $0^{\circ}$ C. The section of the plot where the temperature levels out represents the steady-state temperature of approximately -20°C. Generated using ANSYS.

From this analysis, we can conclude that the internal temperature of our CubeSat will be such that it does not exceed the maximum or minimum operating range of our most temperature-sensitive components. Additional refinement of the model and incorporation of additional thermal coatings into the CubeSat design will bolster the feasibility of the thermal subsystem even further. For this reason, we can conclude that the thermal subsystem, as designed, would be feasible and meet all thermal subsystem requirements.

### 4.7.2 Recommendations for Future Work

Further thermal analysis should be performed. This additional thermal analysis should include internal radiation as well as internal heat sources, such as the CPU and battery. The thermal properties of the various CubeSat components should be further refined according to the final design of the CubeSat. Additionally, more research should be performed in order to determine the best coatings use for the interior and exterior components in the CubeSat's final design in order to achieve the optimal temperature conditions. The ANSYS model should be updated as the design is updated.

### 4.8 Structure

Requirement ID	Structure Subsystem Requirements	Mapping to
		System-Level
		Requirements
STRC-REQ 1	The CubeSat structure must house all hardware within a standard	REQ 1
	CubeSat configuration no larger than 6U.	
STRC-REQ 2	The CubeSat structure must be able to withstand the	REQ 5
	gravitational, thermal, and vibrational loads associated with	
	launch from within its deployment pod.	
STRC-REQ 3	The CubeSat structure must be able to withstand the thermal	REQ 5
	loads it will encounter post-launch for the duration of its mission	
	until end of life.	
STRC-REQ 4	The CubeSat structure must be such that the deployment of	REQ 5
	any/all deployables does not cause any resonant frequencies to	
	be achieved.	

Table 13: Structural Requirements for the Zodi CubeSat Mission

### 4.8.1 Analysis

As stated previously, the structure of our CubeSat will be a standard 4U CubeSat frame in a 20cm x 20cm x 10cm configuration. The 0.745 kg mass of this structure (See Appendix A) was derived from the combination of four modular ISIS CubeSat Structures [26]. This 4U configuration will allow the CubeSat to be deployed using a properly sized CubeSat deployment pod. Until the final design configuration of the Zodi CubeSat is finalized, more in-depth structural-dynamics analysis cannot occur. Because of the standardized nature of CubeSat structures, however, we forsee no reason why this 4U CubeSat will have any difficulties meeting its structural requirements. For this reason, the structure of our CubeSat had been determined to impart no negative impact on the feasibility of the Zodi mission.

### 4.8.2 Recommendations for Future Work

Once the final Zodi CubeSat design in finalized, in-depth structural-dynamics analysis will be required to ensure that the CubeSat survives the gravitational, thermal, and vibrational loads of launch from within its deployment pod. This structural analysis will also need to model solar array deployment and ensure no resonant frequencies are achieved because of it. A third objective of this structural analysis would be to ensure the CubeSat materials do not deform due to the thermal loads it will encounter on its close approach to the Sun. Additionally, because of the limited volume, it will likely not be possible to incorporate meaningful structural radiation shielding, though this possibility is still worth exploring.

## 5 Conclusions

Based on the performed analyses, we can confidently conclude that a 4U CubeSat mission to image the zodiacal dust cloud from above the ecliptic would be highly feasible. The BET-1mN electrospray thruster [13] will be able to perform the necessary  $\Delta v$  burn to achieve the desired periapsis orbital height of 0.1283AU and apoapsis orbital height of 0.2215 after an Earth gravity assist, while only taking up 1U of volume. An ADCS-2120 monochrome image sensor [2] and Cassegrain optical telescope setup [3] will be able to completely image the zodiacal dust cloud at both periapsis and apoapsis in just 9.67 days, with high resolution, and while taking up only 1U of volume. A triple modular redundancy control system comprised of 3 micro-controllers like the Raspberry Pi Model 3B+ [19] will be able to operate the CubeSat autonomously, and all scientific data could be redundantly stored on a 5Gb solid state drive. Four Blue Canyon RWP050 reaction wheels [24] will be able to orient the CubeSat with a fast enough slew to properly collect its images, cancel out the external torques resulting from solar radiation pressure, and do so without ever reaching wheel saturation. A cold-gas RC134a momentumdumping system requiring only 3.7g of fuel will be able to dump all the momentum stored as a result of solar radiation pressure, ensuring that the CubeSat will retain attitude control even if it experiences unexpected external torques. A  $1200 cm^2$  triple-GaAs solar array [20] will be able to fully power the CubeSat at all stages of its mission, even with all hardware operating at maximum wattage. The CubeSat will be able to power itself even during eclipse and partial solar array deployment by housing a 1/3U Li-Ion battery. Thermal analysis confirms that the battery (the most temperature-sensitive hardware on the CubeSat) will be able to continue operating under the maximum and minimum expected temperatures. An OMNI-A0150 X-Band omni-directional antenna [18] and CPUT X-Band transmitter will be able to transmit all scientific data in a reasonable transmission time of 1.93 hours using the NEN or 68 seconds using the DSN. Finally, the Zodi CubeSat will be able to do all of this and still achieve a final volume of just 3.89 U.

It is the opinion of this author at the time of this writing that the Zodi CubeSat Project is ready to move past feasibility analysis, and onto practical modeling, design, & fabrication.

The CubeSat will transmit in the X-Band at 8.45GHz. The X-Band was chosen due to its high datarate capabilities and legacy for deep-space science missions. Based on the CPUT XTX X-Band Transmitter [17] and Alaris OMNI-A0150 High Gain X-Band Omni-directional Antenna [18], a link budget (Table 16 above) was assembled for both the Deep Space Network (DSN) and Near Earth Network (NEN) as potential ground receivers. Based on the CPUT Transmitter datasheet, a RF power of 2W (3dBW) was chosen and the datarate was not allowed to exceed 50Mbps, keeping within the CPUT Transmitter's limits. Similarly, based on the OMNI-A0150 Antenna datasheet, an antenna gain of 4dBi was chosen based on the OMNI-A0150's limits. A satellite line loss,  $L_{line}$ , of 2 dB was assumed based on typical satellite line loss values. From these values, the Equivalent Isotropic Radiated Power (EIRP) was calculated:

$$EIRP = P_{Tx}[dBW] + G_{Tx}[dBi] - L_{line}[dB]$$
$$EIRP = (3.010299957 \ dBW) + (4 \ dBi) - (2 \ dB)$$
$$EIRP = 5.010299957 \ dBW$$

At this transmission frequency of 8.45GHz and distance of 8731km, free space loss,  $L_s$ , amounts to 189.442681dB, as calculated below (where r is distance in km and f is carrier frequency in GHz):

$$\begin{split} L_s &= 92.45 + 20 \log \left( r[km] \right) + 20 \log \left( f[GHz] \right) \\ L_s &= 92.45 + 20 \log \left( 8371 \ km \right) + 20 \log \left( 8.45 \ GHz \right) \\ L_s &= 189.442681 \ dB \end{split}$$

To ensure our communications system will be able to transmit its data under any atmospheric conditions, worst-case atmospheric losses,  $L_a$ , in the X-Band were taken for both the DSN and NEN, resulting in a worst-case atmospheric loss of 0.205dB for the DSN (Canberra DSCC at 99% Availability) and 2.74dB for the NEN (Hawaii at 99% availability). A ground terminal loss,  $L_i$ , of 3 dB was assumed based on typical ground terminal loss values. Combining all external losses,  $L_{Comb}$ :

$$L_{Comb} = L_s + L_a + L_i$$

$$L_{CombDSN} = (189.442681 \ dB) + (0.205 \ dB) + (3 \ dB) = 192.647681 \ dB$$
$$L_{CombNEN} = (189.442681 \ dB) + (2.74 \ dB) + (3 \ dB) = 195.182681 \ dB$$

To ensure our communications system will be able to transmit to ANY ground station in the DSN or NEN, the worst case receiver G/T was taken for both the DSN and NEN, resulting in a worst case G/T of 51.3dB/K for the DSN (worst case for 8.4-8.5 GHz downlink frequency range) and 24.4dB/K for the NEN (Chile, using largest available antenna). Using these worstcase G/T values, the EIRP, and combined external losses ( $L_{Comb}$ ), the receiver Carrier-to-Noise Ratio,  $C/N_0$ , was calculated:

$$C/N_0 = EIRP + G/T - L_{Comb} + 228.6$$

$$(C/N_0)_{DSN} = (5.010299957 \ dBW) + (51.3 \ dB/K) - (192.647681 \ dB) + 228.6 = 92.26261894 \ dB$$
$$(C/N_0)_{NEN} = (5.010299957 \ dBW) + (24.4 \ dB/K) - (195.182681 \ dB) + 228.6 = 62.82761894 \ dB$$

Our transmitter will use QPSK modulation with a 9/10 code rate, resulting in a required signal-to-noise ratio  $\left(\frac{E_b}{N_0}\right)$  of 3.89dB. In order to account for uncertainty, a link margin of at least 3dB was chosen. From this, the maximum allowed datarate,  $R_{b\ Max}$ , (in Mbps) in order to achieve a 3dB link margin was calculated:

$$R_{b\ Max\ DSN} = \frac{10^{(C/N_0) - (\frac{E_b}{N_0}_{Req}) - (LinkMargin)/10}}{1000000\ bps}$$

$$R_{b\ Max\ DSN} = \frac{10^{(92.26261894\ dB) - (3.89\ dB) - (3\ dB)/10}}{1000000\ bps} = 344.5576478\ Mbps$$

$$R_{b\ Max\ NEN} = \frac{10^{(62.82761894\ dB) - (3.89\ dB) - (3\ dB)/10}}{1000000\ bps} = 0.392430\ Mbps$$

The transmitter has a maximum datarate of 50 Mbps, so we chose a 40 Mbps datarate when transmitting to the DSN, and a 0.392430 Mbps datarate when transmitting to the NEN. Because two full horizons of images will take up approximately 1360 Mb and the data storage system incorporates a data redundancy of 2, there will be 2720 Mb of data to transmit to Earth. With our selected datarates, it would take  $\frac{2720 \ Mb}{40 \ Mbps} = 68 \ s$  to transmit this data to the DSN and  $\frac{2720 \ Mb}{0.392430 \ Mbps} = 6931.1724 \ s = 1.9253$  hours to transmit this data to the NEN.

These selected datarates result in the following predicted signal-to-noise ratio  $\left(\frac{E_b}{N_0 P_{red}}\right)$ :

$$\frac{E_b}{N_0}_{Pred} = C/N_0 - 10\log\left(R_b[bps]\right)$$

$$\frac{E_b}{N_0}_{Pred DSN} = (92.26261894) - 10\log(4000000 \ bps) = 16.24201903 \ dB$$
$$\frac{E_b}{N_0}_{Pred NEN} = (62.82761894) - 10\log(392430 \ bps) = 6.889996935 \ dB$$

Thus resulting in the following link margins:

$$Link \ Margin = \frac{E_b}{N_0}_{Pred} - \frac{E_b}{N_0}_{Req}$$

$$Link \ Margin_{DSN} = \frac{E_b}{N_0} \sum_{Pred \ DSN} - \frac{E_b}{N_0} = (16.24201903 \ dB) - (3.89 \ dB) = 12.35201903 \ dB$$

$$Link \ Margin_{NEN} = \frac{E_b}{N_0} \sum_{Pred \ NEN} -\frac{E_b}{N_0} = (6.889996935 \ dB) - (3.89 \ dB) = 2.999996935 \ dB \approx 3 \ dB$$

   \% IMP-8 (for cycle 21), and GOES-5, -6 and -7 satellite data (for cycle
   8 22).
   *Column 1 is proton energy range (in MeV) with energy >E, column 2 is the
   %minimum event fluence, column 3 is the worst case event fluence. For all
45
   %applications, I will be using the worst case event fluence.
   *These values will be further scaled according to an inverse square (1/R
      \leftrightarrow ^{2})
   %dependence on distance from the sun, as all table values were taken from
      \rightarrow a
   %distance of 1AU.
